The growth behavior of tin clusters has been suggested in lighter congeners, clusters of tin have attracted less attention. Atomic structures and the nature of the chemical bonding in tin clusters have been reported to be abnormally high relative to that of the bulk. This finding has drawn significant recent attention to tin clusters, although the nature of the abnormal melting temperature has not been fully elucidated. It is clear that knowledge of the electronic and atomic structures and the nature of the chemical bonding in these clusters would be essential for a proper understanding of their melting behavior or other physical and chemical properties.

I. INTRODUCTION

Atomic clusters of the group 14 elements have been the topic of intensive studies in cluster science because of their major scientific and technological importance. One of the key questions concerns the growth pattern and bonding behavior of these clusters as a function of size. The trend going down the periodic table is fascinating for the group 14 elements, from the semimetallic graphite (or wide band gap diamond) to the semiconductors Si and Ge to the metallic Sn and Pb. Carbon clusters have been found to undergo interesting structural variations with the increase of cluster size from linear chains to monocyclic rings to polycyclic rings to fullerenes and carbon nanotubes. Small Si and Ge clusters seem to exhibit tetrahedral bonding feature found in the bulk semiconductors.1–28 Ion mobility experiments have revealed that they form prolate structures in the smaller size regime and undergo a structural transition to more spherical geometries at the size of several dozen atoms.16–20 Relative to its lighter congeners, clusters of tin have attracted less attention. The growth behavior of tin clusters has been suggested in general to resemble those of Ge and Si clusters on the basis of ion mobility data.29,30 Interestingly, the melting temperatures of tin clusters have been reported to be abnormally high relative to that of the bulk.31 This finding has drawn significant recent attention to tin clusters, although the nature of the abnormal melting temperature has not been fully elucidated. It is clear that knowledge of the electronic and atomic structures and the nature of the chemical bonding in...
and Snₙ clusters share similar structures, whereas Sn₈ and Sn₁₀ have different structures compared with those of the corresponding Si and Ge clusters. A more extensive study of the low lying isomers of neutral Snₙ clusters up to n=20 has been carried out by Majumder et al., who suggested deviations from the growth behavior of Si and Ge clusters in the size range of n > 8.

Photoelectron spectroscopy (PES) of size-selected anion clusters is a powerful technique to probe the electronic structures of atomic clusters. PES studies of tin clusters have been performed by several groups previously. The prior PES results suggest that the photoelectron spectra of Snₙ⁻ clusters are similar to those of Sn₉⁻ and Ge₉⁻ consistent with the ion mobility studies concerning the structural similarity between Sn and Si/Ge clusters. In particular, Negishi et al. reported an extensive set of PES data on Snₙ⁻ clusters and used halogen doping to probe the nature of the electronic structure in Sn₉ and Pb₉ clusters. Their PES data suggested that a small band gap exists in small Snₙ clusters. But the semiconductor-to-metal transition was not conclusively observed due to the limited size range and/or spectral resolution.

All the previous PES works on Snₙ⁻ clusters have been done with photon energies at 4.661 eV (266 nm) or less and at relatively poor spectral resolution. We are interested in probing the electronic structure evolution of Snₙ⁻ clusters, in particular, the semiconductor-to-metal transition, at higher photon energies and improved spectral resolution. High photon energies allow more valence transitions to be observed, whereas the improved spectral resolution would allow more definitive observation of the energy gap. Our improved data immediately revealed that the spectra of Sn₁₂⁻ are unusual relative to those of its neighbors and are totally different from those of Si₁₂⁻ and Ge₁₂⁻. This led to the recent discovery of stannaspherene (Sn₁₂⁻) (Ref. 38) and subsequently plumbaspherene (Pb₁₂⁻), which are highly stable icosahedral cages with large empty interiors analogous to the fullerene C₆₀. The chemical bonding in stannaspherene and plumbaspherene is similar to the well-known B₁₂H₁₂ molecule. The stannaspherene and plumbaspherene cages have diameters larger than 6 Å and can host all transition metal atoms to form a class of stable endohedral cage clusters, even more advantageous than endohedral fullerenes, which cannot entrap transition metal atoms other than the rare earth elements.

In the current work, we report the details of our PES study on Snₙ⁻ (n=4–45) at 193 nm (6.424 eV) and 266 nm (4.661 eV) under well controlled experimental conditions and with improved spectral resolution. The new data allow us to obtain more accurate electron affinities (EAs), as well as better defined spectral features. The energy gap is also better determined, showing a clear closing at n=42, which defines the cluster size of semiconductor-to-metal transition. The trend of the EAs as a function of size also indicates that for n > 41 it follows the metallic droplet model, consistent with the nonmetal to metal transition at n=42.

II. EXPERIMENTAL METHODS

The experiment was carried out using a magnetic-bottle time-of-flight photoelectron spectrometer, details of which have been described elsewhere. The Snₙ⁻ cluster anions were produced by laser vaporization of a pure tin target with a helium carrier gas and analyzed using a time-of-flight mass spectrometer. The Sn₉⁻ (n=4–45) clusters were each mass selected and decelerated before crossing with a detachment laser beam in the interaction zone of the magnetic-bottle photoelectron analyzer. In the current study, two detachment photon energies were used, 266 nm Nd:YAG (4.661 eV) from a (neodymium doped yttrium aluminum garnet) laser and 193 nm (6.424 eV) from an ArF excimer laser. Well resolved photoelectron spectra were obtained by carefully selecting those clusters that had sufficient resident time in the nozzle to be thermalized. We have shown previously that clusters with long resident time in the nozzle are relatively cold, which are essential to yield well resolved PES spectra. Photoelectrons were collected at nearly 100% efficiency by the magnetic bottle and analyzed in a 3.5-m-long electron flight tube. The binding energy spectra were obtained by subtracting the kinetic energy spectra from the photon energies of the detachment laser. The spectra were calibrated using the known spectrum of Au⁻ for the 193 nm spectra and Pt⁻ for the 266 nm data. The apparatus had an electron energy resolution of ΔE/E≈2.5%, i.e., about 25 meV for 1 eV electrons. We also obtained photoelectron spectra for Si₉⁻ and Ge₉⁻ clusters in the smaller size regime under similar experimental conditions for comparison with the Sn₉⁻ clusters.

III. EXPERIMENTAL RESULTS

A. The 193 nm spectra of Snₙ⁻ (n=4–45)

The 193 nm spectra of Snₙ⁻ are shown in Fig. 1 for (n=4–45). For n < 10, spectral features appeared only below 5 eV, but for larger clusters high binding energy features were observed, which could only be accessed at 193 nm. All spectra were well resolved for n ≤ 25 and the PES spectra in this size range showed strong size dependence, where adding or removing one Sn atom produced major changes to the PES spectrum. Relatively simple spectra with well resolved features were observed for clusters with n < 10. For n ≥ 10, the spectral features became more congested, except for Sn₉⁻, which exhibited a relatively simple spectrum with only five resolved features. It was this observation that led to our discovery of stannaspherene previously.

A clear energy gap was observed in most of the PES spectra, where a relatively weak threshold band was followed by an energy gap and more intense transitions at higher binding energies. This observation suggests that the neutral Sn clusters are closed shell and the extra electron in the anion occupies the lowest unoccupied molecular orbital (LUMO) of the neutral system, giving rise to the relatively weak threshold feature. Sn₉⁻ and Sn₁₀⁻ exhibited the largest energy gaps of 0.93 and 1.25 eV, respectively, suggesting that neutral Sn₉ and Sn₁₀ are highly stable clusters. A number of clusters were observed to have relatively small gaps, including n=5, 8, 10, and 12 in the size range below n=25.
For $\text{Sn}_1^{-}$ and $\text{Sn}_2^{-}$, a weak feature (labeled as * in Fig. 1) seemed to be observed in the band gap range, which suggested the existence of potential isomers.

For the cluster size range of $n=26$, the PES spectra were relatively poorly resolved due to the congested electronic transitions and/or the existence of isomers. The threshold transition and a small band gap could still be resolved for all the species up to $n=41$, beyond which no spectral features could be resolved and the PES spectra became essentially continuous abruptly for $n=42–45$. The spectrum of $\text{Sn}_{29}^{-}$ was relatively well resolved and showed the largest band gap of 0.73 eV in this size range, indicating that neutral $\text{Sn}_{29}$ should be an electronically stable cluster. Weak spectral features near the threshold (labeled * in Fig. 1), which could be due to minor structural isomers, were observed in the spectra of $\text{Sn}_{26}^{-}$, $\text{Sn}_{27}^{-}$, $\text{Sn}_{28}^{-}$, and $\text{Sn}_{30}^{-}$. The threshold feature in $\text{Sn}_{29}^{-}$ was not well resolved, possibly also due to the presence of isomers. However, the spectra of $\text{Sn}_{30}^{-}$ and $\text{Sn}_{31}^{-}$ were surprisingly well resolved compared to other species in this size range.

**B. The 266 nm spectra of $\text{Sn}_n^{-}$ ($n=4–31$)**

Figure 2 shows the 266 nm spectra of $\text{Sn}_n^{-}$ for $n=4–31$. The PES spectra of small $\text{Sn}_n^{-}$ clusters ($n=1–12$) at 266 nm have been reported previously by Moravec et al.\textsuperscript{50} Negishi et al.\textsuperscript{51} have reported the 266 nm PES spectra of $\text{Sn}_n^{-}$ for ($n=4–45$). Generally, the current PES spectra are consistent with the previous results, but significantly improved. The spectral resolution of the current study is comparable to that of Moravec et al., but the signal to noise ratios were much improved, in particular, in the higher binding energy side. In all the spectra of Negishi et al., a low energy tail was present likely due to hotter clusters and poor resolution, which led to much lower adiabatic detachment energies (ADEs). For example, the well resolved threshold feature in the current spectra for $\text{Sn}_{12}^{-}$ yielded an ADE of $3.23\pm 0.05$ eV,\textsuperscript{38} which also defines a relatively accurate EA for neutral $\text{Sn}_{12}$. This is in contrast to the 3.0–3.6 eV range reported by Moravec et al. and the much smaller value of $2.35\pm 0.15$ eV reported by Negishi et al. (see Table I).

The 266 nm spectra of $\text{Sn}_n^{-}$ clusters were only taken up to $\text{Sn}_{31}^{-}$ in the current study because of weak photoelectron signals for large $\text{Sn}_n^{-}$ clusters, which led to significant deterioration of spectral qualities, as can be seen in Fig. 2 for $n=30$ and 31 already. Compared with the 193 nm spectra, the data at 266 nm were better resolved for the low binding energy features accessible at this photon energy. The first band of $\text{Sn}_{13}^{-}$ at 193 nm was resolved into two peaks in the 266 nm spectrum, where the second weaker peak (labeled * in Fig. 2) might be due to an isomer. A weak feature was also observed in the highest occupied molecular orbital (HOMO)-LUMO gap region in the 266 nm spectrum of $\text{Sn}_{17}^{-}$, which was not resolved in the 193 nm spectrum and could also be due to a minor isomer. It is also worth pointing out that even though the spectrum of $\text{Sn}_{12}^{-}$ was better resolved at 266 nm (Fig. 2), the uniqueness of this spectrum in comparison with
that of its neighbors was not quite obvious because of the limited spectral range, suggesting the importance of obtaining PES spectra at high photon energies or in general at various photon energies.

C. Adiabatic detachment energies and HOMO-LUMO gaps

The adiabatic detachment energies, which also represent the electron affinities of the corresponding neutral clusters, were difficult to measure in general without vibrationally resolved PES spectra. We estimated the EAs by drawing a straight line at the leading edge of the ground state feature and then adding the appropriate instrumental resolution to the intersections with the binding energy axis. Although this is an approximate procedure, we have been able to obtain consistent EAs from well resolved spectra taken at different photon energies, in particular, for spectra with a sharp onset. The relatively cold clusters in the current study resulted in

*From Ref. 38.
better resolved spectra with sharp onsets, which were important in obtaining accurate EAs. All the reported EAs were determined from the 266 nm spectra wherever available. More accurate EAs were obtained in the lower photon energy spectra because of the better spectral resolution. The obtained EAs are compared with previous measurements in Table I and plotted as a function of size (n) and \( n^{-1/3} \) in Fig. 3.

If a neutral cluster is closed shell, then in the anion the extra electron occupies the LUMO of the corresponding neutral cluster. This extra electron usually yields a weak threshold PES band followed by an energy gap, which represents the experimental measure of the HOMO-LUMO gap in the neutral cluster. This energy gap carries important information about the nonmetal to metal transition in the tin clusters. It usually rules out the ground state also being the cluster radius.

![FIG. 3. (a) Electron affinities (EAs) of Sn\(_n\) \((n=4-45)\) as a function of size \(n\). (b) EA vs \(n^{-1/3}\) \((n^{1/3}\) is proportional to \(1/r\), \(r\) being the cluster radius).](image)

IV. DISCUSSION

A. Sn\(_n\)−Sn\(_{10}\) and comparisons to Si\(_n\) and Ge\(_n\) clusters

In Fig. 5, we compare the PES spectra of Sn\(_n\) for \(n=4\)−13 to those of Si\(_n\) and Ge\(_n\) in the same size range. PES of Si\(_n\) and Ge\(_n\) has been studied extensively previously.\(^{6-15}\)

The current data are slightly better resolved, but otherwise consistent with the previous reports. Clearly, the spectra of the three cluster systems exhibit remarkable similarities for \(n=4\)−7, suggesting that Si, Ge, and Sn clusters possess similar structures in this size range. A number of theoretical calculations have been reported for the structures of small neutral and anion tin clusters.\(^{32-36,44-48}\) The consensus is that the global minima of neutral Sn\(_n\) clusters for \(n \leq 7\) are indeed identical to those previously established for Si\(_n\) and Ge\(_n\) species by PES and IR/Raman spectroscopy in matrices.\(^{12}\)

The relatively large energy gaps observed for \(n=4\) and 7 (Fig. 4) are consistent with their high structural symmetries, a \(D_{2h}\) rhombus for \(n=4\) and a \(D_{5h}\) pentagonal bipyramid for \(n=7\). The structures for \(n=5\) and 6 have been determined to be trigonal and tetragonal bipyramids, respectively.\(^{32,33,46-48}\)

The spectra of Sn\(_7\)−Sn\(_{10}\) are similar to those of the corresponding Ge\(_n\) clusters, but quite different from those of the Si\(_n\) clusters (Fig. 5), suggesting that Sn cluster anions in this size range have similar structures to those of Ge\(_n\) clusters, but different from those of Si\(_n\). Indeed, Sn\(_8\) has been predicted to be a capped pentagonal bipyramid,\(^{32}\) whereas Si\(_8\) is predicted to be a distorted bicapped octahedron (\(C_{2v}\)) and Si\(_8^-\) has been confirmed to be a distorted cube (\(C_{2v}\)/\(C_{3v}\)).\(^{20}\) Our PES spectral pattern for Sn\(_n^-\) displays some similarity to that of Sn\(_7^-\) (Fig. 5), providing indirect support for a capped pentagonal bipyramidal structure for Sn\(_7^-\). Sn\(_8^-\) has been predicted to be a tetracapped trigonal bipyramid,\(^{32}\) which is also very different from the confirmed tricapped prism structure for Si\(_7^-\).\(^{12,20}\) For Sn\(_{10}\), two structures with very close energies have been predicted,\(^{32}\) the lowest energy structure (10a) is a distorted tetracapped prism, similar to that of Sn\(_{10}\).\(^{12,20}\) For Si\(_{10}\), two structures with very close energies have been predicted,\(^{32}\) the lowest energy structure (10a) is a distorted tetracapped prism, similar to that of Sn\(_{10}\) and Si\(_{10}\).\(^{20}\) whereas another isomer (10b) with near \(C_{3v}\) symmetry is predicted to be only 0.09 eV higher in energy.\(^{32}\) The tetracapped prism structure for Si\(_{10}\) gives the large HOMO-LUMO and has been confirmed to be the ground state also for Sn\(_{10}\)\(^{12}\). Thus, the very different PES spectra for Sn\(_{10}\) can easily rule out the (10a) structure for Sn\(_{10}\), suggesting that the near \(C_{3v}\) (10b) isomer is likely to be the ground state for Sn\(_{10}\).

B. Sn\(_{11}\)−Sn\(_{13}\): The unique PES spectra of Sn\(_{12}\) and the discovery of stannaspherene

In a recent communication,\(^{38}\) PES spectra of Sn\(_n^-\) \((n=11-13)\) at 193 nm have been reported and compared to those of Ge\(_n^-\) \((n=11-13)\). In Fig. 5, we compare the spectra of Si\(_n^-\), Ge\(_n^-\), and Sn\(_n^-\) in the same size range. The similarities among the spectra for the 11-mer and 13-mer are obvious,
suggesting that these clusters should all have similar ground state structures. The previous theoretical calculations predicting different structures for Sn11 and Sn13 from the corresponding Si_n clusters are questionable. Both Si11 and Si13 have been confirmed to possess low symmetry C₃s structures. However, the PES spectrum of Sn12 is totally different from those of Sn12⁻ and Ge12⁻ and is also surprisingly simple compared to those of its neighbors, Sn11⁻ and Sn13⁻. The relatively simple and characteristic spectrum of Sn12⁻ immediately suggested that it should possess a high-symmetry structure, which led to our recent discovery of stannaspherene. Our prior theoretical calculations showed that Sn12⁻ is a slightly distorted icosahedral cage due to the Jahn-Teller effect. Adding an electron to Sn12⁻ led to a perfect icosahedral cage Sn12²⁻, which possesses a large empty interior (6.1 Å diameter) and spherical π bonding similar to C₆₀ and was named “stannaspherene” for its near spherical symmetry and π bonding character. The stannaspherene cage is highly stable and it has been shown to be able to trap all transition metal atoms, as well as rare earth atoms, to form a whole new class of stable endohedral clusters.

C. Sn₁₄⁻−Sn₂₅

The PES spectra of Sn_n⁻ in the size range of n=14−25 became increasingly complicated, but were still well resolved at both 193 and 266 nm (Figs. 1 and 2). Ion mobility measurements have suggested that tin clusters of medium size (13 ≤ n ≤ 35) adopt prolate geometries, which are similar to those found for Si and Ge clusters, all exhibiting prolate shapes. The PES spectra of Sn_n⁻ in the size range of n=14−25 display some similarity to those of Si_n⁻, providing additional support for their structural similarities.

In this size range, the PES spectra for several clusters, namely, Sn₁₃⁻, Sn₁₇⁻, Sn₁₉⁻, and Sn₂₂⁻, showed evidence of possible isomeric contributions. In the 266 nm spectrum of Sn₁₃⁻ (Fig. 2), the second weak peak around 3.2 eV (labeled “•••”), which was not resolved in the 193 nm spectrum, was likely due to an isomer. Similarly, a weak feature (•••) was also resolved in the energy gap region in the 266 nm spectrum of Sn₁₉⁻ and Sn₂₂⁻. For Sn₁₉⁻ and Sn₂₂⁻, this feature was fairly intense and in the 266 nm spectrum of Sn₁₉⁻ the second feature was even more intense than the first feature, suggesting the existence of two nearly degenerate isomers. The current data on the Sn_n⁻ clusters in the size range of n=14−25 are sufficiently well reserved and can be used to compare with more detailed theoretical calculations to elucidate the structures of tin clusters in the medium size range.
For $\text{Sn}_n$ clusters with $n > 25$, the PES spectra became more congested and poorly resolved. In a number of cases, the existence of possible isomers (*) was evident, further aggravating the problem. For many species in this size range, only the ground state transition was resolved for $n \leq 41$. For $n > 41$, no features were resolved and the PES spectra became essentially continuous. Ion mobility experiments suggest that tin clusters gradually rearrange towards near spherical geometries in the size range of $n = 35–65$. Our PES spectra indicate that this structural transition may occur around $\text{Sn}_{42}$, since continuous spectra were suddenly observed beyond $n = 42$. The featureless PES spectra may result from the metalliclike behavior of the large tin clusters, as will be discussed below.

In the larger cluster size range, the spectrum of $\text{Sn}_{29}$ was somewhat special with well resolved spectral features and an unusually large energy gap. The most surprising observation was the spectrum of $\text{Sn}_{40}$, which was well resolved in sharp contrast to the nearly continuous spectra in this size range. These observations suggested that $\text{Sn}_{29}$ and $\text{Sn}_{40}$ were likely to have relatively stable and high-symmetry structures. The spectrum of $\text{Sn}_{41}$ was also well resolved and displayed similarities to that of $\text{Sn}_{40}$, suggesting that the additional atom in $\text{Sn}_{41}$ does not distort the $\text{Sn}_{40}$ structure too much and providing strong evidence for the high stability of the $\text{Sn}_{40}$ cluster.

E. EA and HOMO-LUMO gap as a function of size: Semiconductor-to-metal transition

The EAs obtained for $\text{Sn}_n$ from the current work are given in Table I and compared with previously reported values. For $n = 4–8$, our data are consistent with those of Moravec et al., but in the size range of $n = 9–12$, our data are much more accurate because Moravec et al. were only able to give a range of values. Negishi et al. reported EAs for a large set of $\text{Sn}_n$ clusters, but most of their EA values were underestimated because of the poor resolution and the hot band transitions that led to low binding energy tails. Their EAs were in general between 0.2 and 0.5 eV too low. For $\text{Sn}_{12}$, their EA was too low by 0.88 eV. Our EAs are plotted as a function of size in Fig. 3(a). Large size variations are observed for small clusters of $n = 12$. Distinct minima are seen in the EA vs $n$ curve at $n = 4$, 7, 17, 29, 36, and 40. Interestingly, these EA minima correspond to maxima in the HOMO-LUMO gaps (Fig. 4), suggesting that the corresponding neutral clusters exhibit pronounced stability. In Fig. 3(b), we plotted the EAs as a function of $n^{-1/3}$, i.e., $1/r$, where $r$ is the cluster radius and is proportional to $n^{1/3}$. It is seen that the EAs follow in general a straight line, which extrapolates to 4.4 eV at infinite cluster size, very close to the bulk work function of tin (4.42 eV). The EAs for clusters above $n = 42$ fall on the straight line, suggesting that the large clusters can be described by the classical metallic droplet model.

In Fig. 4 we plotted the HOMO-LUMO gaps of $\text{Sn}_n$ clusters as a function of size. All clusters up to $n = 41$ display a HOMO-LUMO gap, suggesting that these clusters are semiconductorlike with a closed shell electronic configuration. The HOMO-LUMO gaps are strongly dependent on the cluster size. In addition to the unusually large gaps shown by $\text{Sn}_4$ and $\text{Sn}_7$, there are other pronounced maxima at $n = 16–18$, 22, 29, 36, and 40, which correspond to the EA minima, as mentioned above. The HOMO-LUMO gap disappeared precipitously for clusters with $n = 42$, suggesting that the larger clusters are metalliclike. The semiconductor-to-metal transition at $n = 42$ is also accompanied by the abrupt change in the PES spectral pattern and the EA vs $1/r$ curve [Fig. 3(b)], which shows that the EAs of clusters above $n = 42$ can be described by the metallic droplet model.

V. CONCLUSIONS

A photoelectron spectroscopy study was carried out for $\text{Sn}_n$ ($n = 4–45$) clusters at two detachment photon energies, 193 and 266 nm, under well controlled experimental conditions to produce relatively cold cluster anions. Well resolved PES spectra were obtained for small clusters with $n = 4–25$ and surprisingly for two large clusters, $\text{Sn}_{29}$ and $\text{Sn}_{40}$. The well resolved spectra can be used to compare with future theoretical calculations to elucidate the detailed structures of the tin clusters. The PES spectra of very small $\text{Sn}_n$ clusters ($n = 4–13$) were compared with those of Si$_n$ and Ge$_n$ clusters, and both similarities and differences were observed, depending on the size. More accurate electron affinities for tin clusters were obtained and the evolution of their electronic structure was systematically investigated. A HOMO-LUMO gap was observed in the PES spectra for clusters with $n = 41$, indicating the semiconductor nature of small tin clusters. A semiconductor-to-metal transition was observed at $n = 42$, beyond which no energy gaps were observed and the PES spectra became featureless and continuous.
