Received: September 11, 2010; Revised Manuscript Received: October 15, 2010

During photoelectron spectroscopy experiments, the spectra of \( \text{B}_{11}\text{O}^- \) and \( \text{B}_{10}\text{Au}^- \) clusters are found to exhibit similar patterns except for a systematic spectral shift of \( \sim 0.5 \) eV, hinting that they possess similar geometric structures. The electron affinities are measured to be \( 4.02 \pm 0.04 \) eV for \( \text{B}_3\text{O} \) and \( 3.55 \pm 0.02 \) eV for \( \text{B}_{10}\text{Au} \). DFT calculations at the B3LYP level show that \( \text{B}_{11}\text{O}^- \) and \( \text{B}_{10}\text{Au}^- \) adopt similar \( ^1\text{A} \) ground states, which are based on the quasiplanar \( \text{B}_{10} \) cluster interacting with a \( \text{BO} \) unit and \( \text{Au} \), respectively. The \( \text{B}_{11}\text{O}^- \) and \( \text{B}_{10}\text{Au}^- \) clusters are thus valent ionic electronic because both \( \text{BO} \) and \( \text{Au} \) can be viewed as monovalent units, forming highly covalent \( \text{B}–\text{BO} \) and \( \text{B}–\text{Au} \) bonds analogous to the \( \text{B}–\text{H} \) bond in \( \text{B}_{10}\text{H}^+ \). For \( \text{B}_{10}\text{Au}^- \), we also find a highly symmetric \( D_{10h} \) planar molecular wheel as a minimum on the potential energy surface. However, it is 45 kcal/mol above the ground state at the B3LYP level and not viable for experimental observation. Natural bond orbital analyses reveal interesting covalent versus ionic \( \text{B}–\text{Au} \) bonding in the \( \text{C}_1 \), \( \text{B}_{10}\text{Au}^- \) and \( D_{10h} \) \( \text{B}_{10}\text{Au}^- \) structures, respectively, providing insight for the design of \( D_{10h} \) MB\textsubscript{n} molecular wheels.

1. Introduction

Boron possesses interesting chemical bonding properties and has played essential roles in advancing chemical bonding models.\textsuperscript{1,2} Primarily due to the electron deficiency of boron, delocalized three-center-two-electron bonds are common in boranes\textsuperscript{9} and elemental boron clusters.\textsuperscript{4–8} Boron also forms interesting oxides, and the simplest diatomic BO molecule (boronyl) has long been recognized as a \( \sigma \)-radical\textsuperscript{9–11} with a \( \text{BO} \) triple bond. BO and \( \text{BO}^- \) are valent ionic electronic to CN and CN\textsuperscript{−}CO, respectively, which are important inorganic ligands. However, despite decades of persistent interest in boron oxides,\textsuperscript{12,13} boronyl chemistry remains relatively unknown.\textsuperscript{14–20}

We are interested in elucidating the electronic structure and chemical bonding of boron oxide clusters using photoelectron spectroscopy (PES) and theoretical calculations.\textsuperscript{11,21–23} We recently characterized two boron oxide clusters,\textsuperscript{22} \( \text{B}_3\text{O}_2^- \) and \( \text{B}_3\text{O}_3^- \), which possess linear \( \text{B}(\text{BO})_2^- \) \( D_{3h}, \Sigma_g^- \) and triangular \( \text{B}(\text{BO})_3^- (D_{3h}, \Sigma_g^-) \) structures, that is, two and three boronyls bonded to a single \( \text{B} \) atom. We further showed that the \( \text{B}_3\text{O}_2^- \) cluster has a linear diboronyl diborene ground state, \( \text{B}_2(\text{BO})_2^- \), which can be viewed as two boronyls bonded to a \( \text{B}_2 \) core and concurrently features a rare \( \text{B}≡\text{B} \) triple bond.\textsuperscript{23} Our combined experimental and theoretical studies\textsuperscript{21–23} have stimulated further theoretical efforts on boron oxide clusters.\textsuperscript{24–27} However, none of the \( \text{B}_n(\text{BO})_m^- (m \geq 2) \) clusters has been characterized experimentally. Among earlier studies relevant to boronyl chemistry, gas-phase microwave\textsuperscript{14} and matrix infrared spectroscopy\textsuperscript{15} suggested rather strong \( \text{B}–\text{O} \) linkage in XBO. PES data revealed a similarity between \( \text{H}_2\text{CBO} \) and its isoelectronic \( \text{H}_2\text{CCN} \),\textsuperscript{16} and thus the \( \text{B}–\text{O} \) linkage in the former was described as a triple bond. Very recently, the first metal boronyl compound featuring a \( \equiv \text{BO} \) triple bond was synthesized in the bulk.\textsuperscript{18}

The bonding properties of \( \text{Au} \) in alloy clusters represent yet another interesting aspect in cluster research.\textsuperscript{28–30} The isolobal analogy between a gold phosphine unit and a hydrogen atom has helped the rationalization of the structure and bonding in \( \text{Au} \) compounds.\textsuperscript{28} Further analogy between a bare \( \text{Au} \) atom and \( \text{H} \) has been discovered recently in gas-phase binary \( \text{Au} \) clusters.\textsuperscript{31–35} In systematic studies on \( \text{Si}–\text{Au} \) clusters, \( \text{SiAu}_n \) \((n = 2, 3), \text{Si}_2\text{Au}_n \) \((n = 2, 4), \) and \( \text{Si}_3\text{Au}_n \) were shown to possess structures and bonding similar to the silane \( \text{Si}_n\text{H}_n \) \( D_{2n} \) \( \Sigma_g^- \) unit.\textsuperscript{36} The \( \text{B}_{10}\text{Au}^- \) cluster in the current work serves as another example to further test the \( \text{Au}/\text{H} \) analogy in \( \text{Au} \) alloy clusters. Moreover, stimulated by the elucidation of the chemical bonding in planar boron clusters,\textsuperscript{5–7} there is increasing computational interest in planar \( \text{MB}_n \) molecular wheels.\textsuperscript{37–44} Among these \( \text{MB}_n \) clusters are the \( \text{D}_{10h} \) \( \text{B}_{10}\text{Au}^- \) and \( \text{D}_{10h} \) \( \text{B}_{10}\text{Zn} \) species.\textsuperscript{40} However, the viability of all these \( \text{D}_{10h} \) molecular wheels has yet to be confirmed experimentally.

Here we report a combined PES and theoretical study of \( \text{B}_{11}\text{O}^- \) and \( \text{B}_{10}\text{Au}^- \) clusters. During PES experiments on boron oxide clusters and \( \text{B}–\text{Au} \) alloy clusters, \( \text{B}_{11}\text{O}^- \) and \( \text{B}_{10}\text{Au}^- \) are observed to exhibit similar PES patterns except for a slight shift in binding energies. Theoretical calculations show that \( \text{B}_{11}\text{O}^- \) and \( \text{B}_{10}\text{Au}^- \) possess similar \( ^1\text{A} \) ground-state structures, where the \( \text{B}_{11}\text{O}^- \) cluster can be described as \( \text{B}_{10}\text{(BO)}^- \), that is, a boronyl \( \equiv \text{BO} \) unit interacting with an aromatic \( \text{B}_{10} \) core. Both the \( \text{B}–\text{BO} \) and \( \text{B}–\text{Au} \) bonds are shown to be highly covalent, analogous to the \( \text{B}–\text{H} \) bond. The current study highlights not only the robustness of the \( \equiv \text{BO} \) boronyl group in boron-rich boron oxide clusters but also the \( \text{Au}/\text{H} \) analogy in \( \text{B}–\text{Au} \) complexes. A highly symmetric \( D_{10h} \) \( \text{B}_{10}\text{Au}^- \) molec-
ular wheel is shown to be a high-lying minimum 45 kcal/mol above the C1 ground state. The bonding of this cluster is compared with that of the C1 global minimum, providing insight into the stability of D_3b-type MB_n molecular wheels.

2. Experimental and Computational Methods

2.1. Photoelectron Spectroscopy. The experiments were carried out using a magnetic-bottle PES apparatus equipped with a laser vaporization cluster source, details of which have been described previously.45,46 Briefly, the B_{11}O^- cluster anions were produced by laser vaporization of a pure disk target made of enriched ^{10}B isotope (99.75%) in the presence of a helium carrier gas seeded with 0.01% O_2. The B_{10}Au^- clusters were produced using an Au/B mixed disk target (^{10}B isotope enriched, 99.75%) and a pure helium carrier gas. Cluster anions from the laser vaporization source were analyzed using a time-of-flight mass spectrometer. The B_{11}O^- and B_{10}Au^- clusters of current interest were each mass-selected and decelerated before being photo-detached. Two detachment photon energies were used in the current experiments: 266 nm (4.661 eV) and 193 nm (6.424 eV). Effort was made to choose colder clusters (that is, those with long resident times in the nozzle) for photodetachment, which was shown previously to be important for obtaining high quality PES data.47 Photoelectrons were collected at nearly 100% efficiency by the magnetic bottle and analyzed in a 3.5 m long electron flight tube. The PES spectra were calibrated using the known spectra of Rh^- and Au^-. The energy resolution of the apparatus was ∆E_D/∆E_k ~ 2.5%, that is, ~25 meV for 1 eV electrons.

2.2. Computational Methods. Structural optimizations were carried out using the hybrid B3LYP level,47 with the augmented Dunning’s all-electron basis set (aug-cc-pvtz)49 for B, O, and H and the Stuttgart relativistic small-core pseudopotential and valence basis set augmented with two f and one g functions [Stuttgart_rsc_1997_ecp + 2fg: α(f) = 0.498, α(g) = 1.461, α(g) = 1.218] for Au.50 A variety of initial structures were optimized in search of the ground-state structures of B_{11}O^- and B_{10}Au^- and their neutrals. For the purpose of comparison, the same set of structures was also calculated for B_{10}H^- and B_{10}H. Frequency calculations were done to confirm that all obtained ground-state structures are true minima. Excitation energies of the neutrals were calculated with the time-dependent DFT (TDDFT) method51,52 at the ground-state structures of the anions. All calculations were carried out using Gaussian 03.53

3. Experimental Results

3.1. B_{11}O^- . The PES spectrum of B_{11}O^- at 193 nm is shown in Figure 1. Its electron binding energies turn out to be rather high. Two well-separated bands (X and A) are revealed between 4 and 5 eV. The ground-state band X is relatively sharp, with

![Figure 1. Photoelectron spectrum of B_{11}O^- at 193 nm (6.424 eV).](image1)

![Figure 2. Photoelectron spectra of B_{10}Au^- at (a) 266 nm (4.661 eV) and (b) 193 nm (6.424 eV).](image2)

![Table 1: Observed Adiabatic and Vertical Detachment Energies (in eV) for B_{11}O^- and B_{10}Au^- , Compared to the Calculated Binding Energies Based on the C_{1v} (1A) Anion Ground-State Structures (1 for B_{11}O and 7 for B_{10}Au^-) at B3LYP and TDDFT Levels.](table1)
the electron affinity of B10Au neutral. The relative intensities of bands X and A seem to show photon-energy dependence. Such photon-energy-dependent intensity changes can in principle give valuable information about the nature of the electrons being detached. However, in the current case, the detachment channels for the X and A bands are both from delocalized orbitals of the B10 ring as will be shown later, and no such information can be extracted from the photon-energy-dependent intensity changes.

The overall PES pattern of B10Au at 193 nm (Figure 2b) is surprisingly similar to that of B11O (Figure 1), except for a systematic shift to lower binding energies (≈0.5 eV; see Table 1). Again, an energy gap (≈1.1 eV) is observed between bands A and B. Bands B (5.05 eV) and C (5.20 eV) partially overlap with each other. The higher binding energy portion of the 193 nm spectrum shows numerous features beyond 5.5 eV (Figure 2b), all appearing to be relatively sharp. Three major bands are labeled: D (5.59 eV), E (5.85 eV), and F (6.07 eV).

4. Theoretical Results

Structural searches for the B11O− and B10Au− clusters can be demanding computationally. Fortunately, the PES similarities between B11O− and B10Au− (Figures 1 and 2) strongly hint that the two species are structurally similar and, therefore, should both possess a B10 moiety. Our structural searches are thus largely based on the B10 unit, with the extra BO unit and Au attached to different possible sites. Selected optimized structures for B11O− (1−5) and B10Au− (7−12), along with the ground-state structures of their neutrals (6 and 13), are shown in Figure 3.

Briefly, structures 1 (C1, 1A), 2 (C1, 1A′), and 3 (C3, 1A) of B11O− can be viewed as the BO unit being attached terminally to three possible peripheral sites of the quasiplanar B10− cluster6 in an in-plane fashion. The BO unit prefers a corner site, resulting in anion ground state 1. Structures 2 and 3 are first-order saddle points, ≈40 kcal/mol higher than structure 1. Structure 5 (C2, 1A1) can be considered as the BO unit being attached perpendicular to the plane, which is a third-order saddle point, ≈86 kcal/mol above structure 1. Structure 4 (C2, 1A1) is based on the B11− moiety6 with the O atom attached to a peripheral site. It is a second-order saddle point, ≈74 kcal/mol above structure 1. The neutral state 6 (C1, 1A) is located as a true minimum, which corresponds to the anion ground state 1.

Selected structures for B10Au− (7−12) and B10Au (13) are shown in Figure 3b. Their ground states are 7 (C1, 1A) and 13 (C1, 2A), respectively. Among these optimized structures, 7, 9, 10, 12, and 13 correspond to structures 1, 3, 4, 5, and 6 for B11O−/B10O, respectively. Note that structures 8, 9, 10, and 12 are not minima. Also located for B10Au− is a highly symmetric wheel structure: 11 (D1h, 1A1g), which is a true minimum substantially higher in energy (by 45 kcal/mol). To aid the elucidation of chemical bonding in B11O− and B10Au−, a similar set of structures are also optimized for B10H− (14−18) and B10H (19), as shown in Figure 4.

5. Comparison between Experiment and Theory

The well-resolved PES spectra of B11O− and B10Au− (Figures 1 and 2) provide electronic and structural information, which helps the search for the global minimum structures through comparison between experiment and theory. As shown in Table 1, the calculated ground-state ADE and VDE for B11O− (1) are 3.82 and 3.94 eV, respectively, as compared to the experimental values of 4.02 and 4.08 eV. For B10Au− (7) the calculated ground-state ADE (3.33 eV) and VDE (3.50 eV) may be compared with the experimental values of 3.55 and 3.64 eV, respectively. It is seen that B3LYP consistently underestimates the ground-state ADE by ≈0.2 eV and VDE by ≈0.15 eV. For the numerous excited states, TDDFT calculations reproduce the experimental VDE values within ≈0.1 eV for the majority of PES bands (Table 1).

The simulated PES spectra for B11O− and B10Au− are shown in Figure 5, both in excellent agreement with the experimental data. In particular, the small X−A energy gap and the relatively large A−B energy gap, which are characteristic of the experi-
mental PES spectra, are perfectly borne out in the TDDFT calculations. The agreement between experiment and theory is remarkable, lending considerable credence to the identified ground-state structures for both B\(_{11}\)O\(^-\) and B\(_{10}\)Au\(^-\) and their neutrals.

6. Discussion

6.1. Structural Similarities between B\(_{11}\)O\(^-\), B\(_{10}\)Au\(^-\), and B\(_{10}\)H\(^-\). The similarity in the PES spectra of B\(_{11}\)O\(^-\) and B\(_{10}\)Au\(^-\) is surprising at first glance, suggesting that these two clusters may possess similar structures. The key to the structural connection between B\(_{11}\)O\(^-\) and B\(_{10}\)Au\(^-\) is the occurrence of the B\(_{10}\) unit and the peripheral BO group in B\(_{11}\)O\(^-\) (Figure 3a). Both BO and Au can be viewed as monovalent species, which are bonded to the same peripheral site on the B\(_{10}\) unit (Figure 3). It is noted that the B\(_{11}\)O\(^-\) (I) ground-state structure, B\(_{10}\)BO\(^+\), differs substantially from that of the bare B\(_{11}\)\(^-\) cluster, indicating the predominant role of the BO group in governing the structures of boron-rich oxide clusters. The structures of B\(_{11}\)O\(^-\) and B\(_{10}\)Au\(^-\) (Figure 3) may be compared to that of B\(_{10}\)H\(^-\) (Figure 4). The three anion species possess similar global minimum structures (I, 7, and 14), all involving a B\(_{10}\) structural unit, with BO, Au, and H bonded to the same peripheral corner site. The similar structures for B\(_{10}\)X\(^-\) (X = BO, Au, H) underlie the electronic and structural robustness of the doubly (\(\sigma\) and \(\pi\)) aromatic B\(_{10}\) cluster as an inorganic building block.

6.2. Chemical Bonding in B\(_{10}\)X\(^-\) (X = H, Au, BO). The B\(_{10}\)\(^-\) cluster has a C\(_3\) (C\(^\infty\)) ground state whose valent molecular orbitals (MOs) are depicted in Figure 6a. The highest occupied molecular orbital (HOMO) is filled by a single electron in the anion. Out of the 15 fully occupied MOs, 9 (HOMO–6 and HOMO–8 through HOMO–15) are responsible for the eight peripheral two-center-two-electron (2c–2e) B–B bonds and one 2c–2e bond between the two inner B atoms. The remaining six MOs are responsible for the delocalized global bonding: three MOs (HOMO–1, HOMO–2, and HOMO–7) for the global \(\pi\)-bonding and three MOs (HOMO–3, HOMO–4, and HOMO–5) for the global \(\sigma\)-bonding. Thus the B\(_{10}\) neutral possesses double (\(\pi\) and \(\sigma\)) aromaticity.

In B\(_{10}\)H\(^-\) (14) the B\(_{10}\) moiety retains intact. Except for minor distortions, all 15 fully occupied MOs of B\(_{10}\)\(^-\) can be found in B\(_{10}\)H\(^-\) (HOMO through HOMO–9, and HOMO–11 through HOMO–15; Figure 6b), confirming the structural integrity of the B\(_{10}\) moiety. The HOMO–10 in B\(_{10}\)H\(^-\) (Figure 6b) represents the new bonding MO, which may be traced back to the singly occupied HOMO of B\(_{10}\) (Figure 6a). However, this MO is now composed heavily of the H 1s atomic orbital and primarily represents the B–H single bond.

Compared to B\(_{10}\)H\(^-\), B\(_{10}\)Au\(^-\) (7) has five more MOs due to the 5d electrons (Figure 7). Despite some mixture with the Au 5d orbitals, the 15 MOs responsible for the bonding in the B\(_{10}\) unit can be identified: nine (HOMO–6, HOMO–9, HOMO–11, HOMO–13, and HOMO–16 through HOMO–20) for the localized 2c–2e B–B bonds and one 2c–2e bond between the center B atoms, three MOs (HOMO, HOMO–2, and HOMO–10) for the global \(\pi\)-bonding, and three MOs (HOMO–1, HOMO–3, and HOMO–4) for the global \(\sigma\)-bonding. Five out of six remaining MOs (HOMO–5, HOMO–7, HOMO–8, HOMO–12, and HOMO–14) involve primarily Au 6s/5d atomic orbitals, although B–Au bonding interactions can be
Bonding in B$_{11}$O$^-$ and B$_{10}$Au$^-$ Clusters

seen in HOMO$\rightarrow$5, HOMO$\rightarrow$12, and HOMO$\rightarrow$14. HOMO$\rightarrow$15 is the key MO which is responsible for the B$\rightarrow$Au σ-bonding. This MO is equivalent to the B$\rightarrow$H σ-bonding orbital in B$_{10}$H$^-$ (14, HOMO$\rightarrow$10; Figure 6b).

B$_{10}$(BO)$^-$ (1) possesses 40 valence electrons, which occupy 20 MOs as shown in Figure 8. Again, 15 of these MOs can be easily identified for bonding in the B$_{10}$ unit: the localized peripheral 2c$\rightarrow$2e B$\rightarrow$B bonds and one 2c$\rightarrow$2e bond between the two-center B atoms (HOMO$\rightarrow$5, HOMO$\rightarrow$6, HOMO$\rightarrow$8, HOMO$\rightarrow$10, HOMO$\rightarrow$14 through HOMO$\rightarrow$18), delocalized global π-bonding (HOMO, HOMO$\rightarrow$2, and HOMO$\rightarrow$7), and delocalized global σ-bonding (HOMO$\rightarrow$1, HOMO$\rightarrow$3, and HOMO$\rightarrow$4). Among the remaining MOs, HOMO$\rightarrow$9, HOMO$\rightarrow$11, and HOMO$\rightarrow$12 are responsible for B$\equiv$O bonding in the boronyl group, whereas HOMO$\rightarrow$19 is the O 2s lone pair. The key bonding MO (HOMO$\rightarrow$13) is primarily responsible for the B$\rightarrow$BO single σ-bond, which links the B$_{10}$ core and the peripheral BO group. Indeed, HOMO$\rightarrow$13 is nearly identical to the corresponding HOMO$\rightarrow$10 of B$_{10}$H$^-$ (Figure 6b) and HOMO$\rightarrow$15 of B$_{10}$Au$^-$ (Figure 7), all of which stem from the σ-bonding interaction between the singly occupied B$_{10}$ σ HOMO and the H, Au, or BO radicals.

Thus, B$_{10}$X$^-$ (X = H, Au, BO) anions can be considered as covalent complexes between a doubly (σ- and π-) aromatic B$_{10}$ core and a monovalent σ-radical, which are linked through a single B$\rightarrow$X σ-bond. The calculated B$\rightarrow$X bond distances at the B3LYP level are 1.184 Å for B$_{10}$H$^-$ (14), 2.029 Å for B$_{10}$Au$^-$ (7), and 1.628 Å for B$_{10}$(BO)$^-$ (1), which are all typical values for single B$\rightarrow$X bonds.$^{23,33,36}$ Other than the B$\rightarrow$X bond, both B$_{10}$ and X in B$_{10}$X$^{-}$ maintain their structural and chemical integrity. For example, the BO group in B$_{10}$(BO)$^-$ (1) retains its triple bond character (HOMO$\rightarrow$9, HOMO$\rightarrow$11, and HOMO$\rightarrow$12; Figure 8), and the B$\equiv$O bond distance (1.215 Å at the B3LYP level) matches that of free BO (1.203 Å).$^{11}$ As seen from Figures 6–8, the top few occupied MOs (e.g., HOMO through HOMO$\rightarrow$4) are similar for B$_{10}$(BO)$^-$, B$_{10}$Au$^-$, and B$_{10}$H$^-$, which underlies the similarity of the PES spectra for B$_{10}$O$^-$ and B$_{10}$Au$^-$.

The negative charge in the B$_{10}$X$^-$ anions is located on the B$_{10}$ unit (see the HOMOs of B$_{10}$X$^-$). Therefore, the B$\rightarrow$X covalent bond is similar in the ground states of B$_{10}$X$^-$ and B$_{10}$X. The B$\rightarrow$X bond distances are elongated only very slightly in the neutrals relative to their anions: 0.004 Å for B$_{10}$H$^-$, 0.028 Å for B$_{10}$Au, and 0.010 Å for B$_{10}$O.

6.3. On the Viability of the Hypercoordinate D$_{10h}$ B$_{10}$Au$^-$ Molecular Wheel. The quest of planar hypercoordinate molecular wheels is primarily stimulated by the discovery of pure boron molecular wheels.$^{5–8}$ Hypercoordinate molecular wheels containing a boron ring such as D$_{6h}$ CB$_6^{2-}$, D$_{7h}$ CB$_7^-$, C$_{2v}$

![Figure 8. Valence molecular orbital pictures for C$_1$ (1A) B$_{10}$O$^-$ (1).](image)

![Figure 9. Simulated photoelectron spectrum (solid line) based on the D$_{10h}$ (1A$_g$) B$_{10}$Au$^-$ (11) anion structure, as compared with the 193 nm experimental data (dashed line). The simulated spectrum is constructed by fitting the distribution of calculated vertical detachment energy values with unit-area Gaussian functions of 0.05 eV width.](image)

(effectively D$_{6h}$) CB$_6$, D$_{7h}$ AlB$_6$, and D$_{9h}$ FeB$_7$ have been suggested computationally.$^{37,41–43}$ However, recent joint experimental and theoretical studies have shown that D$_{6h}$ CB$_6^{2-}$, D$_{7h}$ CB$_7^-$, and D$_{9h}$ CB$_9$ are highly unstable and that carbon avoids the hypercoordinate central position in these species.$^{38}$ The highest coordination number in a planar environment observed experimentally to date is eight in the B$_{10}$ molecular wheel.$^{1}$ A similar molecular wheel with a noncoordinate Al has been proposed for AlB$_6$.$^{43}$ There has been interest to design even larger boron rings with a center metal atom, such as the D$_{10h}$ B$_{10}$Au$^-$.$^{39}$

Our structural searches indeed find a true D$_{10h}$ (1A$_g$) minimum for B$_{10}$Au$^-$ (11, Figure 3). However, at the B3LYP level it is 45 kcal/mol above the C$_1$ (1A) ground state (7), and it is not viable experimentally. The simulated PES spectrum based on the D$_{10h}$ B$_{10}$Au$^-$ anion is shown in Figure 9, where it is compared with the 193 nm experimental PES spectrum. Because of the high symmetry of the D$_{10h}$ isomer, its simulated PES spectrum only contains two peaks in the binding energy regime of 3–6.3 eV. This spectral pattern completely disagrees with the observed PES spectra for B$_{10}$Au$^-$, confirming the B3LYP result that the D$_{10h}$ isomer is much higher in energy.

Why is the D$_{10h}$ (1A$_g$) B$_{10}$Au$^-$ (11) minimum so much higher in energy relative to the C$_1$ (1A) B$_{10}$Au$^-$ (7) ground state? The D$_{10h}$ B$_{10}$Au ring is intrinsically electron deficient and would require electron donation from the center atom in the molecular wheel.$^{39}$

NBO analyses reveal that the Au center, which has the natural electronic configuration of 6s$^0$6p$^4$6d$^{10}$, carries a positive net atomic charge of +0.14 $\epsilon$ (BO) structures, the integrity and double 3.7 eV,$^{57}$ provides additional B1159

In conclusion, we report a combined photoelectron spectroscopy and density functional theory study on B$_{11}$O$^-$ and B$_{10}$Au$^-$.
clusters, which give similar PES spectra. DFT calculations show that B\(_11\)O\(_4\) and B\(_{10}\)Au\(_{7}\) possess similar C\(_1\) (\(\text{\(^a\)}\)) structures, which are based on the quasiplanar B\(_10\) unit with BO and Au bonded to the same peripheral corner site. B\(_11\)O\(_4\) and B\(_{10}\)Au\(_{7}\) are thus valence isoelectronic, consistent with their similar PES spectra. The B–BO and B–Au bonding are shown to be highly covalent, analogous to the B–H bonding in B\(_2\)H\(_6\). A highly symmetric D\(_{2h}\) \(\text{\(^a\)}\) molecular wheel is located as a minimum for B\(_{10}\)Au\(_{7}\), 45 kcal/mol above the ground state. The current results reinforce the importance of boronyl as a structural unit and the hydrogen analogy of Au, and shed light on the design of D\(_{2h}\)-type MB\(_n\) molecular wheels.
